Introduction: Over 150 mutations have been identified in the ADAMTS13 gene in patients with congenital thrombotic thrombocytopenic purpura (TTP). The majority of these (86%), lead to reduced (<50%) secretion of mutant recombinant ADAMTS13. The mechanism by which this occurs has not been investigated in vitro. Two novel ADAMTS13 mutations (p.I143T and p.Y570C) identified in two congenital adolescence onset TTP patients were studied, to investigate their effects on ADAMTS13 secretion and subcellular localisation.

Materials and Methods: HEK293T cells were transiently transfected with wild type or mutant ADAMTS13 cDNA. Immunofluorescence and confocal microscopy were used to study localisation within the endoplasmic reticulum (ER) and Golgi. The cell proteasome and lysosomes were inhibited in cells stably expressing ADAMTS13 to investigate degradation of ADAMTS13 by either organelle.

Results: Both mutations severely impaired secretion and both mutants localised within the ER and Golgi. Proteasome inhibition led to the intracellular accumulation of both mutants, suggesting proteasome degradation. Lysosome inhibition on the other hand did not lead to increased intracellular accumulation of the mutants.

Conclusions: Proteasome degradation of these ADAMTS13 mutants contributed to their reduced secretion.

1. Introduction

Thrombotic thrombocytopenic purpura (TTP) patients have an acquired or congenital deficiency in ADAMTS13 activity [1–3]. ADAMTS13 processes and cleaves Von Willebrand factor (VWF) at the Tyr1605-Met1606 peptide bond in the A2 domain [4,5]. Its deficiency leads to the accumulation of ultra-large VWF (ULVWF) multimers within the circulation, leading to the uncontrolled formation of platelet-rich thrombi in the microcirculation and subsequent vessel occlusion.

Congenital TTP patients are presently treated with plasma infusion/exchange which provides a source of ADAMTS13. Despite these patients typically having severely reduced ADAMTS13 activity, the clinical presentation and response to treatment is highly variable. Evidence suggests that the ADAMTS13 genotype may account for some of this heterogeneity. Over 150 mutations have been identified throughout the ADAMTS13 gene in patients with congenital TTP [1,6–19] and relationships appear to exist between ADAMTS13 genotype, age of disease onset [20] and residual ADAMTS13 activity [11]. Residual ADAMTS13 activity in turn appears to be associated with the annual rate of TTP episodes and with the requirements for fresh frozen plasma prophylaxis [11].

As residual ADAMTS13 activity appears to be associated with disease severity and with ADAMTS13 genotype, it is important to understand how different ADAMTS13 mutations affect its function. Of the mutations identified, approximately 30% have been expressed in vitro [7,20–22]. These mutations affect to various degrees the secretion and activity of ADAMTS13 [20]. The majority (86%), lead to reduced (<50% of wild type [WT]) secretion of mutant recombinant ADAMTS13, suggesting misfolding of ADAMTS13 and subsequent retention and degradation by the cell. The mechanism by which this may occur however has not been investigated in vitro.

With this in mind we studied two novel previously uncharacterised mutations (p.I143T, p.Y570C) present in a homozygous form in two different congenital TTP patients [17,23]. Both of these mutations are located within the N-terminal region of ADAMTS13. The p.I143T mutation is located within the metalloprotease domain which contains the catalytic site necessary for VWF cleavage [24]. The p.Y570C mutation localises within the spacer domain which is important for VWF binding [25–27]. The clinical history of both patients has been described previously [17], but in brief both presented with acute TTP during adolescence with undetectable ADAMTS13 activity and antigen and both receive prophylactic plasma infusion every three to four weeks. The effect of
these mutations on ADAMTS13 secretion was assessed along with their effect on the intracellular localisation of ADAMTS13.

2. Materials and Methods

All reagents were obtained from Sigma Aldrich Chemical Company Ltd. (Poole, UK) unless stated otherwise.

2.1. Site Directed Mutagenesis

The p.I143T (c.428 T > C) and p.Y570C (c.1709 A > G) ADAMTS13 mutations were introduced by site directed mutagenesis into a pcDNA 3.1/V5-His TOPO® vector (Life technologies, Paisley, UK) containing the complete ADAMTS13 cDNA as previously described [28], primers are available upon request.

2.2. Transient and Stable Line Expression

HEK 293T cells were transiently transfected with WT or mutant ADAMTS13 cDNA as previously described [21], along with 1 μl of pRL-TK plasmid (Promega, Southampton, UK) to normalize the transfection efficiency. The pRL-TK vector expresses Renilla luciferase which produces luminescence in the presence of its substrate (luminol). The Renilla luciferase assay system (Promega) was used to measure luminescence in cell lysate samples according to the manufacturer’s recommendations. The luminescence values were used to normalize antigen and activity results. DMEM media was exchanged for OptiMEM media just before transfection. Supernatant and cell lysate samples were harvested four days after transfection as previously described [28].

Stable lines expressing WT or mutant ADAMTS13 were created as previously described [28]. WT and mutant supernatant from transiently transfected cells was concentrated 20 fold, whereas WT and mutant supernatant from stable lines were concentrated 100 fold using centrifugal filter devices with a 100 kDa cut-off (Millipore UK Ltd., Livingston, UK).

2.3. Western Blotting

For SDS-PAGE on transient transfection samples, the volumes loaded were normalized according to the transfection efficiency. Samples were loaded onto 4–12% Bis-Tris polyacrylamide gels (Bio-Rad Laboratories Ltd., Hemel Hempstead, UK) and protein was transferred onto 0.45 μm nitrocellulose membranes (GE Healthcare, Little Chalfont, UK). A primary mouse anti-V5 monoclonal antibody (Life technologies) against the C-terminal V5 tag expressed by the recombinant protein was used, followed by an ECL anti-mouse IgG HRP secondary antibody (GE Healthcare) for supernatant samples. For cell lysate samples membranes were also incubated with an anti-β actin antibody loading control (Abcam, Cambridge, UK) after proteasome and lysosome inhibition. Membranes were developed using supersignal west pico chemiluminescence substrate (Millipore UK Ltd., Livingston, UK) followed by exposure onto Amersham Hyperfilm ECL (GE Healthcare).

2.4. ADAMTS13 Antigen and Activity

ADAMTS13 antigen in supernatant samples from transiently transfected cells was measured using in an house ADAMTS13 antigen ELISA [29] (detection limit 3% of pooled normal plasma (PNP)). ADAMTS13 antigen in supernatant samples from proteasome and lysosome inhibition experiments was measured using an Imubind ADAMTS13 antigen ELISA (Sekisui Diagnostics, Stamford, USA) (detection limit <60 ng/ml, ~6% PNP) as one of the antibodies for the in house ELISA is no longer commercially available. ADAMTS13 activity in supernatant samples was measured using FRETs-VWF73 as substrate [30] with minor modifications [31] (detection limit 5% of PNP).

2.5. Confocal Microscopy

ADAMTS13 localisation within the cell endoplasmic reticulum (ER) and Golgi was investigated using immunofluorescent labelling and confocal microscopy, with antibodies directed against ADAMTS13 and either the ER or Golgi. HEK 293T cells transiently transfected with ADAMTS13 cDNA were fixed with 4% paraformaldehyde, permeabilised with 0.2% Triton and blocked overnight with 3% BSA containing 0.3 M glycine. A chicken anti-V5 primary antibody (Cambridge Biosciences Ltd., Cambridge, UK) and either a mouse anti-GM130 (BD Biosciences, Oxford, UK, cis Golgi marker) or a mouse anti-PDI (protein disulphide isomerase) primary antibody (R190 Abcam, Cambridge, UK, ER marker) was used. A rabbit FITC conjugated anti-chicken antibody (Life technologies) was used to detect the primary anti-V5 antibody. A goat Cy3 conjugated anti-mouse antibody (Millipore UK Ltd) was used to detect the ER/Golgi primary antibody. Cells were mounted with Vectashield® mounting media containing DAPI to stain for nuclei (Vector Laboratories Ltd., Peterborough, UK). Four to six slides were imaged per experiment, over an area of 4.84cm².

Cells were viewed at room temperature using a spinning disk confocal microscope (Perkin Elmer, Massachusetts, USA) with a Velocity acquisition system, built on a Zeiss inverted microscope. Images were captured using either a ×63 or ×100 immersion oil objective both with a 1.4 numerical aperture. Wavelengths for excitation vs. emission were as follows: DAPI, 405 nm vs. 455/460 nm; FITC, 488 nm vs. 527/555 nm and Cy3 568 nm vs. 615/670 nm.

2.6. Quantitation of Cis Golgi Colocalisation

The degree of colocalisation between ADAMTS13 and the cis Golgi was quantified using Velocity 3D analysis software (Perkin Elmer). Clearly defined cells containing unsaturated voxels (throughout the Z-stack) were used for analysis. The threshold Pearson Correlation Coefficient (TPCC) [32] and M1 and M1,M2 Manders overlap colocalisation coefficient (M1) [32,33] were measured. For both types of analysis a ‘threshold’ was set to exclude background voxels, only voxels above this threshold were used for analysis. This was set by selecting a region containing no cells, the average voxel intensities within this region of interest plus 3 standard deviations was then calculated by the software. Threshold values for each channel (FITC: 527/555 nm, Cy3: 515/670 nm) were calculated separately. The same threshold values were used throughout the analysis. Images from three separate experiments were used for analysis. Analysis was restricted to regions containing ADAMTS13 expressing cells. The numbers of cells analysed were as follows: WT (n = 35), p.I143T (n = 29) and p.Y570C (n = 52). Values are expressed as mean ± SEM.

The TPCC gives a value for the correlation between the intensity distributions of the components (Golgi and ADAMTS13) whereas the overlap between the intensities can be described by the coefficient M1. Here M1 represents the sum of the intensities of the ‘red’ Golgi expressing voxels which are colocalised with the green ADAMTS13 voxels divided by the sum of the intensities of all the red (Golgi) voxels [32,33].

2.7. Proteasome and Lysosome Inhibition

Proteasome and lysosomes were inhibited initially in HEK 293T cells transiently transfected with WT or mutant ADAMTS13. However the results from this were unreliable due to differences in the transfection efficiency which could not be normalized using the pRL-TK vector. Instead HEK 293 cells stably expressing WT or mutant ADAMTS13 cDNA were incubated with either 10 μM MG132 (Merck Chemicals, Nottingham UK), 6 μM ALLN (Merck chemicals, prepared in DMSO), 0.1 μM Bafilomycin A1 (prepared in DMSO), or 0.1% DMSO (volume added equivalent to greatest volume of drug added). DMEM media was exchanged for OptiMEM media prior to inhibitor incubation. After 5 h cell lysate and supernatant samples were harvested and analysed. The
ADAMTS13 antigen and activity measured in the supernatant in the presence of inhibitors or DMSO in a given experiment were expressed as a proportion of the values measured in the absence of any inhibitor or DMSO to normalize the results. WT and mutant values in the absence of inhibitor and DMSO i.e. ‘control’, was arbitrarily chosen as 1. The mean ± SEM of these normalized values are shown.

2.8. Densitometry

Densitometry was used to quantify the amount of ADAMTS13 within cell lysate samples after proteasome or lysosome inhibition. Image J software was used for analysis (http://imagej.nih.gov/ij/).

2.9. Statistical Analysis

Unpaired two-tailed Student’s t-tests were used for analysis of differences between colocalisation coefficients, when the mean of WT and mutant coefficients were compared. For statistical analysis of normalized data (antigen, activity and densitometry), differences between the mean of normalized data and a hypothesised mean of 1 (i.e. no difference) were tested. A probability (p) value of < 0.05 was considered significant.

3. Results

3.1. Transient Transfection

ADAMTS13 was detected within the cell lysates of WT and mutant transiently transfected cells (Fig. 1A). No ADAMTS13 protein could be detected in the cell supernatant using western blotting (Fig. 1B) or an ADAMTS13 antigen ELISA and consequently no activity could be detected. Under similar conditions WT ADAMTS13 antigen (n = 3) was 96% (633 ng/ml) (WT and mutant transfected cells were treated in the same way, data was normalized to take into account the transfection efficiency, i.e. number of cells transfected, WT and mutant supernatant harvested after the same amount of time and both concentrated 20 fold).

3.2. Confocal Microscopy

As both mutants appeared to be synthesised within the cell, but secreted at a severely reduced level, their localisation within elements of the secretion pathway was investigated. WT and mutant ADAMTS13 localised extensively within the ER (Fig. 2A). Similarly WT ADAMTS13 localised within the cis Golgi (Fig. 2B), as did both mutants. However the degree of localisation in the cis Golgi appeared to be less extensive for the mutants compared to WT.

Subsequently the degree of colocalisation between the cis Golgi and WT or mutant ADAMTS13 was quantified. TPCC values were slightly lower for the mutants (p.I143T: 0.20 ± 0.016; p.Y570C: 0.20 ± 0.011) compared to WT (0.27 ± 0.013). These differences were statistically significant for both the p.I143T (P = 0.0009) and p.Y570C mutants (P = 0.0002). Similarly, the mean M1 coefficient was slightly lower (p.I143T: 0.87 ± 0.024; p.Y570C: 0.81 ± 0.023) for both mutants compared to WT (0.89 ± 0.027). This difference was statistically significant for the p.Y570C mutant (P = 0.0167) but not the p.I143T mutant (P = 0.4650).

3.3. Proteasome and Lysosome Inhibition

Fig. 1. Western blot analysis of cell lysate and cell supernatant samples harvested from HEK293T cells transiently expressing WT, p.Y570C or p.I143T mutant ADAMTS13. Cell lysate (A) and supernatant (B) samples were harvested 96 h after transfection. Samples were loaded onto 4–12% Bis-Tris polyacrylamide gels. WT and mutant supernatant was concentrated ~20 fold for analysis. ADAMTS13 expected size ~190 kDa. Results shown are representative of three experiments.
ADAMTS13 activity increased slightly with DMSO, but not to the extent observed with MG132. Similarly for the p.Y570C mutant a slight increase in ADAMTS13 levels was observed (antigen: 2.4 ± 1.1, activity: 2.5 ± 1.3). For the p.I143T mutant ADAMTS13 localised within the ER and the cis-Golgi as demonstrated by confocal microscopy. ADAMTS13 localisation in the ER (A) and cis-Golgi (B) is shown. Cells were viewed using a Perkin Elmer Ultraview spinning disk confocal microscope at room temperature and images were acquired using Hamamatsu 9100-500 camera and Volocity software. Cells were mounted with Vectashield mounting media (Vector laboratories). FITC labelled ADAMTS13 is shown in green, Cy3 labelled ER or Golgi in red, DAPI labelled nuclei in blue and a merged image of all channels is shown on the far left to demonstrate colocalisation. Cells shown in A were viewed with an original magnification of x 630, numerical aperture 1.4, cells in B with an original magnification of x 1000, numerical aperture 1.4.

4. Discussion

Studies of the impact of the ADAMTS13 mutations found in congenital TTP on protein function are important as certain mutations may be associated with a higher degree of protein misfolding and/or secretion defect and have a more severe clinical phenotype. Greater understanding of the effect of various mutations on protein secretion and function may contribute to changes in patient management, prophylaxis and therapy.

We have studied two mutations present in a homozygous state in two congenital TTP patients who first presented with disease during adolescence and now require plasma infusion every three to four weeks [17]. The p.I143T mutation present in patient one is situated within the metalloprotease domain, which contains the catalytic site necessary for VWF cleavage. The p.Y570C mutation present in patient two is located within the spacer domain, which is important for VWF binding [25-27]. This amino acid forms part of the surface aromatic cluster on the outer surface of a beta sheet [39]. In vitro expression of these mutations showed that they both severely impaired the secretion of ADAMTS13; no ADAMTS13 antigen or activity could be detected in the supernatant harvested after transient transfection, even after concentrating ~20 fold. After concentration, WT ADAMTS13 antigen levels in this experimental system were similar to those found in PNP (average 96% of PNP, 633 ng/ml). These in vitro results were in agreement with the fact that ADAMTS13 antigen and activity were undetectable in the patient’s plasma (~1% PNP) [11,17].

In order to study the intracellular processing of the mutant proteins, immunofluorescence confocal microscopy and proteasome/lysosome inhibition experiments were performed. Secretory proteins journey through the ER and Golgi where they undergo post-translational modification and folding. Confocal microscopy demonstrated that WT and mutant ADAMTS13 localised within the ER and the cis Golgi.
Localisation of the mutants in the cis Golgi appeared to be less extensive for the mutants and so we attempted to quantify differences in the localisation between the cis Golgi and WT or mutant protein. Quantitative analysis revealed statistical differences between WT and mutant TPCC suggesting reduced correlation between ADAMTS13 and the cis Golgi in the mutants. There was a significant difference between the M1 coefficient for WT and the p.Y570C mutant, suggesting that there was reduced overlap between the cis Golgi and ADAMTS13 in this mutant. There was a large variation in the measured TPCC and M1 in the individual cells analysed. Perhaps to detect significant differences between the M1 coefficient and WT and the p.I143T mutant a larger number of cells would need to be analysed.

Transiently transfected cells were used for confocal microscopy because stable line cells were not available at the time of analysis. One of the weaknesses of using transiently transfected cells is that the level of expression in each transiently transfected cell may differ. Consequently both high and low expressing cells were included in the quantitation analysis. Low expressing cells can have higher colocalisation possibly because the higher concentrations of fluorescent protein saturates high affinity sites and also occupy sites with lower affinities, whereas lower concentrations are confined to the high affinity sites. This may account for the variability in the colocalisation coefficients measured in different cells expressing the same ADAMTS13 form (i.e. WT or mutant).

Misfolded or aggregated proteins are targeted to the proteasome or lysosomes for degradation and so we investigated whether the...
mutants were degraded by either organelle. Proteasome inhibition using MG132 led to increased intracellular levels of both mutants. These results indicate that degradation of the mutants occurs in the proteasome whereas WT ADAMTS13 showed no significant degradation by this route. Targeting of the mutant to the proteasome for degradation would prevent its secretion from the cell. ALLN is a calpain, cathepsin, cysteine protease and proteasome inhibitor [34]. MG132 and ALLN have been shown to increase intracellular levels of other proteins [43].

Fig. 4. ADAMTS13 antigen and activity measured in supernatant samples. Values are represented as mean ± SEM. For analysis of WT, n = 7 and for the mutants n = 3. The dotted line indicates values in the absence of inhibitor and DMSO, i.e. 1. Half the detection limit (2.5%) was used in the analysis for samples from some experiments where ADAMTS13 levels for the p.I143T mutant and p.Y570C mutant were below the detection limit (5%), in order to calculate mean values. Student’s t-test P values are shown below each diagram. **p<0.01.
44], however only MG12 was shown to increase the mutant ADAMTS13 levels, this may be because it is a more specific proteasome inhibitor, compared to ALLN.

Increased intracellular levels of WT ADAMTS13 could be measured after treating HEK 293 cells with Bafilomycin A1, suggesting that a proportion of WT ADAMTS13 is degraded by lysosomes. These organelles unlike proteasomes predominantly degrade aggregated proteins [45] suggesting that some WT ADAMTS13 may be degraded within the cell, this could be due to the high levels of ADAMTS13 expressed within the HEK 293 cells used in this system. The vector expressing ADAMTS13 contained a CMV promoter which would result in high ADAMTS13 levels, perhaps greater than physiological levels. Aggregation of WT ADAMTS13 may be due to the system used to express ADAMTS13 rather than this being a normal feature of ADAMTS13 synthesis. There did not appear to be increased levels of the mutants within the cell after lysosome inhibition suggesting that this organelle is not a significant degradation route for these proteins. It is possible that the mutant proteins were degraded by the proteasome before they had the opportunity to aggregate, or that the structural changes introduced by the mutations prevented their aggregation.

Proteasome inhibition appeared to lead to a slight increase in the levels of the p.I143T mutant, however these differences were small and levels of p.I143T antigen and activity in these experiments were very close to the detection limit. With the p.Y570C mutant a marked increase in levels after the addition of MG12 could be observed. MG12 has been shown to activate the unfolded protein response, which leads to an increase in chaperones and folding enzymes to enhance the folding of misfolded proteins [46]. Furthermore perhaps by inhibiting the proteasome, there was longer retention of the mutant within the ER or Golgi, which would have led to a greater amount of time in which the protein could fold and be subsequently secreted.

4.1. Conclusions

Both the p.I143T and p.Y570C mutations severely impaired ADAMTS13 secretion. The mutants were synthesised within the cell and localised within elements of the secretion pathway (ER and Golgi) suggesting that progress from the Golgi was impeded. The misfolded mutants appeared to be predominantly degraded by the proteasome as intracellular levels increased in the presence of proteasome inhibitors.
